Abstract

Upon achieving ignition and gain, the Laboratory Microfusion Facility (LMF) will be a major tool for inertial Confinement Fusion (ICF) research and defense applications. Our concept for delivering ~10 MJ with a peak on-target light ion power of ~700 TW involves a multi-modular approach using an extension of the compact inductively isolated cavity and Magnetically Insulated Transmission Line (MITL) Voltage Adder technology that presently being used in several large accelerators at Sandia/New Mexico. The LMF driver design consists of twelve 8-TW and twelve 38-TW accelerating modules, each with a triaxial MITL/Adder that delivers power to a two ion extraction diode. The desired energy, power pulse shape, and deposition uniformity on an ICF target are achieved by controlling the energy and firing sequence of the "A" and "B" accelerator modules, plus optimizing the beam transport and focusing. The multi-modular configuration reduces risk by not scaling significantly beyond existing machines and offers the flexibility of staged construction. It permits modular testing at the full LMF operating level.

Introduction

An artist's concept of how one version of the LMF light develop is shown in Fig. 1. Three 15-m high levels could contain the 24 accelerator modules (eight per level) in a closely packed, symmetric arrangement. Also shown are the extended MITLs that converge on the central target section that includes the extraction diodes and the chromatic lens transport and focusing system. The main concern of this paper addresses the conceptual design of the accelerator pulsed-power components. Marx generators, Intermediate Storage Capacitors (ISC), and Pulse Forming Lines (PFL) that operate at >4 MV are within the current technology. An inductive cavity design that provides a 2.0 to 2.5-MV, ~1-MA, ~80-ns pulse to the MITL/Adder appears to be a reasonable extension of present Sandia accelerators such as HERMES-III. In addition to some design and modeling details, our discussion includes ramped pulses that support ion bunching, vacuum stack inductance and cavity diameter considerations, and trade-offs between fewer higher stressed components and many lower stressed components.

Fig. 2 Ion power pulse shape required to ignite target.

A-Modules: The lower power modules are based on components identical to those of HERMES-III. Each of 24 HERMES-III cavities will be driven by two 5-kV, 1.1-MV, 60-ns PFLs. The matched load current is 440 kA. The present HERMES-III accelerator consists of 20 cavities, each driven by four PFLs (about 20% lower total voltage, but twice the current). Because that machine has been thoroughly discussed elsewhere, this paper will be concerned with the B-modules and focus on new aspects of our designs.

B-Modules: The B-modules meet the higher power requirements, while remaining comparable in size to the A-modules, by scaling up both the voltage and current and in the new components. Seventeen cavities in this accelerator will each be powered by four 8-kV, 2.25-MV (average), 80-ns PFLs that supply up to 1.3 MA peak current to a matched load. (It would take approximately 40 HERMES-III cavities to provide the same power.) Figure 3 is a layout of the B-module. According to our conceptual design, the overall module dimensions are about 24 m wide, 32 m long, and 5 m high. The total transformer oil volume for each B-module is approximately 1800 m³. The pulse shaping section between the Marx generators and the cavities delivers a power gain of 19 with an energy transfer efficiency above 50%. The new hardware includes triaxial ISCs for efficient, compact, high voltage pulse shaping and stepped impedance PFLs to provide the desired voltage ramp for taking advantage of ion bunching.
Fig. 3 The B-module accelerator as presently conceived.

MITL/Adder, Diode, and Transport Sections

Each module has two voltage adders and concentric extended MITLs to separately drive the two stages of the ion diode as indicated in Fig. 4. The vertical dashed line in Fig. 3 indicates which portions of the accelerator drives each of the two stages. The MITL operating impedances for the A-modules and B-modules are 2.5 and 2.0 Ω, respectively. The MITLs will be undermatched at the diode to boost the load current and compensate for sheath current losses. The leading edge of the pulse is expected to suffer about 10 ns of erosion due to propagation in the long MITLs.

Table I lists the total electrical parameters delivered to the diodes by all of the twelve A and twelve B modules, respectively.

Our present choice for an LMF light-ion source is the 2-stage extraction diode. This diode offers improved control over the beam energy and current for either bunching or monoenergetic beams. The 2-stage LMF diode parameters are designed to keep enhancement and divergence low, offering a potential divergence reduction to 6 mrad. A flat voltage profile at about 10 MV will drive the first stage 1-cm gap of the LMF diode. A current ramping from 0.8 to 1.1 MA in this gap, due to an assumed impedance drop, will be injected into the second accelerating gap. To accomplish the desired bunching in the B-modules, the injected current will be driven by a second stage accelerating voltage pulse with a 40-ns ramp. The pulse from the second stage MITL/Adders varies from about 16 to 26 MV. The beam inner and outer radii at 8 and 12 cm, respectively, at the 2-cm gap. The ion beam leaving each diode will have about a 32% voltage ramp and 38 TW peak power.

Figure 4 shows how the pulsed power accelerator, diode, and ion transport parameters are defined by the target requirements, assuming a 70% power efficiency from the diode to the target. The 20-ns long main power pulse will arrive at the 1.0-cm radius target with a 0.6-c FWHM Gaussian beam. The baseline transport scheme for LMF is a 4-m achromatic magnetic lens system with the geometry of Fig. 4. The ion bunching occurs throughout the entire transport distance. With the diode solenoid-target achromatic system, focusing is not a function of voltage. The on-axis barricades shield the diodes from line-of-sight debris and radiation damage. A typical system would have a solenoid parameter (B,L) of 82 T-cm and function with 1 Torr of helium.

Modeling and Design Techniques

We used the SCREAMER circuit simulation code for the majority of our initial analysis, because this code is convenient, fast, and inexpensive. It gives reliable results when all the distributed parameters that contribute some effect are included in the circuit model. The code topography allows a single main branch plus end branches which cannot form closed loops. Within this limit we modeled the full line from the Marx generator through to the gaps that drive the MITL/Adder. The block diagram of the SCREAMER circuit model for the LMF B-module in Fig. 5 shows how all the addition parallel PFLs are lumped together and treated as end branches to achieve a realistic waveform propagating through the cavity. SCREAMER generates output pulse tables that can be incorporated as inputs to drive completely independent models starting at that point, the giving a consistent electrical model of the complete accelerator including the MITL/Adders and diode loads. A more general and flexible network simulation, SUPER-SCEPTRE, was used to confirm some details that had been simplified with the SCREAMER circuit, such as the saturation and current loss properties of the cavity isolation cores. The JASON electrostatic solver program was a valuable tool for balancing the high stress electric fields and measuring region capacitances during the design of the inductive cavities and the ISCs.

Fig. 5 Block diagram for LMF B-module circuit model.
Marx Generators

The primary energy storage/sources for each of the MF B-modules as indicated in Fig. 3 are the eight oil-isolated Marx generators, very similar to those developed for the Particle Beam Fusion Accelerator (PBFA-II). The Marxes are composed of 80 (five rows), 3 μF, 100 kV spark gaps. These six each power eight PFLs via two ISCs. They will produce about 745 kJ at 5.5 MV when impulsively charged to 91 kV, and will drive the second stage MITL/Adder. The remaining two Marx generators will have an additional row of capacitors since they must each power ten PFLs to drive the first stage. They will reduce about 975 kJ at 6.3 MV when charged to 95 kV.

Intermediate Storage Capacitors

One-half of the 6-MV, 22-nF, triaxial ISC is shown in Fig. 6. A pair of ISCs couple each Marx generator to eight PFLs (ten for the first stage). As an intermediate pulse shaping stage, the ISC shortens the FL charging time and improves the energy transfer efficiency. With the middle cylinder charged to high voltage, we take advantage of the inner and outer ionized water volumes and reduce the outside dimension to a more manageable size than the conventional coaxial capacitor would allow at these field stresses. For purposes of analysis it can be treated as nested coaxials in series, with the inner and outer radii of 28.2/109 cm and 110/175 cm, respectively, giving an effective impedance of 2.3 Ω. The small length of this water bottle is 2.5 m. From timing breakdown formulas, the largest ratio of average electric field stress to the calculated breakdown stress (F) is 0.8 at the outside of the charged conductor. Peak field stresses on the 4-in thick polyurethane water barrier are kept below 100 kV/cm with an average of 80 kV/cm. With a charging time of 1.35 μs, the ISC for the first and second stages reach 312 MV and 260 kJ at 5.1 MV, respectively.

Inductively Isolated Cavities

A cross section of the 2.5-MV, 23-nH inductive cavity showing the Vacuum Insulator Stack (VIS) and the inductive isolation cores is seen in Fig. 7. The cavity inductance requirement and by the mechanical aspect ratio of average output pulse risetime. It is driven down by overall hardware size and cost. Circuit simulations using our B-module cavity parameters generate the desired ramped output waveforms as defined by the PFL shape. Examples of cavity output voltage and power pulse shapes for a 6-μs to 10-μs PFL model are seen in Fig. 8.

Our switch of choice for discharging the ISCs is the PA-II Rimfire switch which is presently operating near LMF switching parameters. Since the low-jitter, laser-pumped, SF6-filled switch will require only minor modifications to increase its stand-off voltage by ~10% and peak transfer current by ~25% (to 640 kA), no significant design effort has been spent on the new switch. Our circuit simulations modeled the Rimfire switch as a 400-nH inductor in series with an exponentially increasing resistance using an e-folding time constant of 2.6 ns. It closes at about 89% of the ringover peak.

Pulse Forming and Transmission Lines

Because the first gap of the 2-stage diode will require relatively flat voltage pulse shape to drive it, and the end gap needs a specified voltage ramp, two PFL netwires are necessary. The first stage PFL will be a 6-μs coaxial line with a deionized, deaerated water screen. After trying a variety of shapes for the inner conductor in our circuit models, we have selected our second stage PFL to have a "stepped" geometry as indicated in Fig. 6. This novel dual-impedance PFL is easy to make, as well as to model. While the average impedance is still 8 Ω, the slope of the final ramp is sensitive to the spread of the first and second PFL impedances around the average. For our particular circuit model parameters, a 7-μs to 9-μs step results in a 40-ns ramped output with a ΔV/V0 of about 34%, while a larger 6-μs to 10-μs step produces a -41% ramp.
As indicated in Fig. 7, seven toroidal cores of 5.08-cm ribbon-wound amorphous metal alloy, such as the type 2605 CO Metglas by Allied Corp., or the Vitrovac 7600 Z by Vacuumschmelze, are sufficient to provide the 0.18 Volt-sec inductive isolation between neighboring cavities. Our design assumes a 3.3-T AB-swing and 0.7 core packing factor. The number of the cores and the thickness of the insulators separating them are determined by the electric fields. We kept the average field stress along the vertical faces of these cores below 15 kV/cm. The core inner and outer diameters are about 79 cm and 100 cm, respectively. In the SUPER-SCEPTRE circuit model we simulate the core loss/saturation effect by treating the magnetic cores as time-varying, nonlinear resistors in series with a fixed inductor that represents the saturated core inductance; these act as current shunts across the output load. The effective nonlinear resistance is a mixed function of geometry, material properties, and circuit parameters.

Vacuum Insulator Stacks

Seven 5.08-cm thick Lucite insulator rings and six 0.74-cm thick aluminum grading rings form the VIS, as shown in Fig. 7. Since the diodes and target section are far removed from the VISs, the insulators should not suffer degradation from ultraviolet or x-radiation. The length of the stack was chosen so the average electric field stress would be 70 kV/cm for a 2.5-MV applied voltage. Accounting for the pulse length and multiple-cavity large area effects, we estimate the average stress to breakdown as 70 kV/cm. Longer stacks would appear to improve this safety margin, but they also increase the voltage overshoot which begins to negate the improvement.

Another trade-off in the VIS design is field grading uniformity versus cost. Using more, thinner rings will result in a more uniformly graded field across the total length of the VIS. Our initial design efforts, an eight-insulator stack will see +14%/-8% excursions about the average compared to +IS%/-11% with seven insulators far removed from the VISs, the insulators should not suffer degradation from ultraviolet or x-radiation. The positive polarity MITL may be less efficient than the negative polarity configuration. Also, there may be time-dependent divergence losses at the target. The final LMF design evolves as we continue to apply creative component development and learn from component performance on the PBFA-II, HERMES-III, Sabre, and Cornell University machines, among others.

This work was supported by the U.S. Department of Energy under contract DE-AC04-76DP00789. Our appreciation is extended to Don Cook for his encouragement and guidance. For providing us with so many figures that clearly express our intent, we thank Gary Douglas of Rockwell Power Systems. Special thank goes to the Ignition Concepts Review Panel that met on May 14-15, 1992 and, upon a detailed briefing, responded with their findings and recommendations. Panel member include John Greenly of Cornell University; Tom Hussey Phillips Lab; Ian Smith and Phil Spence of Pulse Science Inc.; and Cliff Mendel, Ken Prestwich, Jim Rice, and Ju Ramirez (Chairman) of Sandia Labs.
