ABSTRACT

Man-made vibrations caused by construction activities, blasting, rail and vehicular traffic, and machinery can have an adverse impact on buildings and facilities, human occupants of buildings, and sensitive equipment housed within these facilities. Comparisons between vibrations are often difficult because of different methods used to measure, analyze, and interpret vibration data. To facilitate these comparisons, standard methods of selecting and mounting transducers, processing vibration data, and interpreting test results are reviewed. Specific measurement and analysis techniques and maximum allowable vibration criteria used for evaluating the influence of vibrations on humans, the potential for cosmetic damage to structures, and the impact on vibration-sensitive equipment are also summarized.

KEYWORDS

Construction vibrations, blasting, traffic, pile driving, signal processing, vibration criteria

INTRODUCTION

Ground vibrations arising from man-made sources including construction activities, blasting, and vehicle and rail traffic may interfere with surrounding residential and commercial activities. Ground-borne vibrations can also cause cosmetic and structural damage to nearby structures. The problems may occur as a result of large amplitude vibrations, from repeated occurrences of smaller amplitude vibrations, or from differential settlement induced by particle rearrangement. Ground-borne vibrations are often accompanied by air-borne noise, annoying and heightening the sensitivity of humans. Their concerns often result in legal complaints alleging disruption with daily activities or damage to existing structures.

To assess the impact of ground-borne vibrations on humans and to ensure the safety of existing structures, vibrations arising from construction activities, blasting, and vehicle and rail traffic are often monitored, especially in congested urban and suburban areas. Several state-of-the-art papers and books have sought to characterize and summarize available vibration data (Wiss, 1981; Skipp, 1984; Dowding, 1985; Massarch, 1993; Dowding, 1996). Each of these works, as well as numerous other articles in the literature, have focused on different aspects of vibrations including:

- Classifying types of vibrations and categorizing sources according to the type of vibration they generate.
- Discussing instrumentation available for monitoring and measuring vibrations.
- Establishing relationships between peak particle velocity, energy, and attenuation.
- Demonstrating the difference between levels perceptible to humans and those that cause structural damage.
- Establishing limiting criteria for vibration amplitudes and comparing the limits set forth by governing bodies throughout the world.

Upon reviewing the literature, it is difficult to make comparisons and draw conclusions from different sources of vibration data because of the lack of consistent methods of measuring, processing, and reporting the data. Civil engineers would benefit from the increased availability and adherence to standards that recommend proper procedures for measuring and analyzing this information. The purpose of this paper is to review existing standards and methodologies for measuring vibrations and assessing their impact on humans, structures of various types, and sensitive equipment.
Vibrations resulting from construction activities, blasting, and vehicle and rail traffic can be classified as either continuous or transient based on the duration of the ground motion compared to the time constant describing the response of the structure of interest (ISO, 1990). The time constant is defined as:

$$\tau_r = \frac{1}{2\pi \xi f_r}$$  (1)

where $\xi$ is the damping ratio associated with a particular mode of vibration and $f_r$ is the resonant frequency of that mode. If the duration of the ground motion exceeds $5\tau_r$, the motion is regarded as continuous. Transient ground motions impinge on the structure for durations less than $5\tau_r$. Examples of continuous vibration sources include vibratory pile drivers and traffic. Blast-induced vibrations are typical of transient events. A third category, intermittent vibrations, is often defined to include repetitive, transient excitation such as that resulting from impact pile driving. The distinction between the types of excitation is important because it influences the choice of measurement and processing techniques.

The type of excitation and typical frequency ranges are shown for several man-made vibration sources in Table 1.

Dowding (1996) also provides a wealth of information on the characteristics of various man-made vibrations.

Another useful means of categorizing vibration data is the distinction between deterministic and random data (Fig. 1). The choice of signal processing methods often depends on whether the data may be considered stationary (i.e., has statistical properties which are independent of time). Bendat and Piersol (1989) describe tests used to determine if a signal is stationary.

Fig. 1 Classification of Vibration Signals (from ISO, 1990)

**GENERAL MEASUREMENT AND ANALYSIS TECHNIQUES**

**Measurement Techniques**

Equipment selection is an important aspect of vibration measurement and analysis. Typically, a monitoring system consists of transducers (usually geophones or accelerometers), amplifiers, filters, and a recording system. The transducers produce a voltage output that is proportional to either particle velocity (geophones) or particle acceleration (accelerometers). Individual transducers measure vibrations in one of three orthogonal directions (usually vertical, transverse, and radial). It is common to house three transducers in a case to permit measurements in all three directions simultaneously.

Each transducer has a frequency response curve that determines the voltage output for a given particle motion (Fig. 2).

It is important to select a transducer with a frequency range corresponding to that of the expected ground or structural motion (Table 1). The frequency response function also describes the phase shift introduced by the transducer. In addition, the manner in which the transducer is coupled to the ground or measurement surface has an influence on the accuracy of the recorded motion as described later in this paper.

The frequency response curve may be used to convert the signal from volts to engineering units (e.g., cm/sec). Farnfield (1996) has demonstrated that erroneous results can occur from using a single-valued calibration constant (approximately 13 volts/in./sec in Fig. 2) corresponding to the high-frequency portion of the frequency response curve. More accurate results are obtained if the frequency response curve is applied...
directly to the measured signal in the frequency domain. Farnfield noted that correcting only for the amplitude response of the transducer (and not the phase response) also leads to measurement errors.

Amplifiers and/or filters used as part of the measurement system also have an influence on the recorded motion. For example, low or high pass filters can be used to improve the signal-to-noise ratio, but can produce undesired changes in the amplitude and phase of the signal if not properly selected.

Analysis Techniques

The basic quantity used for analysis of civil engineering vibrations is either the particle acceleration, a(t), or particle velocity time history, v(t), corrected for the influence of the transducer and measurement system as described above. A variety of techniques are available for characterizing these signals including (ISO, 1992):

- peak values and duration for transient vibrations,
- root-mean-square (rms) values for continuous vibrations,
- Fourier, power, octave, and one-third octave spectra, and
- response spectra.

In this section, these basic signal processing and analysis techniques are reviewed. Techniques particular to assessing the impact of the vibrations on humans, structures, and equipment are described in later sections.

It is common to characterize vibration data by identifying the maximum absolute (peak) amplitude of the time history (e.g., Siskind et al., 1980). This method has obvious value because it is simple and reflects the maximum response, but provides an incomplete description of the time history. An alternative is to determine the maximum sustained response defined, for instance, as the third or fifth largest absolute amplitude contained in the time history (Nuttli, 1979).

If particle motions are measured in three orthogonal directions simultaneously, it is possible to calculate the vector sum of the three components using:

$$|v_i| = \sqrt{v_{x_i}^2 + v_{y_i}^2 + v_{z_i}^2}$$

(2)

The root-mean-square (rms) amplitude is more representative of the entire time history and is defined as:

$$v_{\text{rms}} = \sqrt{\frac{1}{N} \sum_{i=1}^{N} v_i^2}$$

(3)

The rms amplitude is strongly dependent on the duration of the record or portion of the record used in the calculation. This is particularly true for transient events in which the duration of the largest motions is small compared to the total length of the recording. One possible solution is to choose a minimum amplitude of interest and calculate the rms amplitude from the time that the minimum amplitude is exceeded for the first time to the time that the minimum amplitude is exceeded for the last time in the record (Bolt, 1969). The choice of minimum amplitude would depend on whether the impact on humans, structures, or sensitive equipment is of interest. A similar approach was used by Siskind et al. (1980) in calculating the velocity exposure level (VEL):

$$\text{VEL} = 10 \log_{10} \left( \frac{1}{T} \int_{t_0}^{T} v^2(t) \, dt \right)$$

(4)

where $t_0$ and $T = 1$ second.

In addition to measures of the amplitude of a vibration time history, the frequency content of the signal is also important in assessing its impact on humans, structures, and sensitive equipment. The simplest method of estimating the frequency content is to estimate the period by examining "zero crossings" of the time history. This method works reasonably well for simple, periodic signals, but is more difficult to use for complex, multiple-frequency signals and tends to underestimate the actual frequencies (Siskind, 1996).

A common method of estimating the frequency content (spectrum) of a signal is to calculate the Fourier transform of the signal:
Generally, plots of the magnitude of the complex-valued Fourier transform are examined to identify peaks corresponding to dominant frequencies in the signal. A related quantity which is also widely used to estimate the frequency content of a signal is the power spectrum:

$$X[k] = \sum_{n=0}^{N-1} x[n] e^{-j2\pi kn/N}$$  \hspace{1cm} (5)

for \( k = 0, 1, 2 \ldots N-1 \)

Despite its widespread use, there are several limitations associated with the use of Fourier methods of estimating spectra. First, the use of Fourier methods implicitly assumes that the signal is stationary. For transient signals such as impact pile driving and blasting and for many continuous signals, this assumption is not valid. For non-stationary signals, the Short Time Fourier Transform, Wavelet Transform, and Wigner-Ville Distribution are examples of techniques which may be used to estimate the instantaneous spectrum of the signal as a function of time (Gade and Gram-Hansen, 1997).

Second, the Fourier-based power spectrum is an inconsistent estimate of the true spectrum of a signal (Kay, 1988). When applied to a single time history, the estimated mean value of the power spectrum approaches the true mean value as the length of the record increases. However, the standard deviation of the estimated value is equal to the mean. This may result in rapidly fluctuating power spectra from which it is difficult to reliably identify peaks corresponding to dominant frequencies. One possible solution is to average the power spectrum of several time histories if the vibration source is repetitive. The standard deviation of the averaged estimate decreases in proportion to the number of averages, but the mean value will be less accurate. Kay (1988) also describes other methods of spectral estimation which often provide superior results to Fourier-based methods (see Table 2).

If it is possible to measure the vibrations impinging on a structure or piece of equipment, the transfer function between the input and output can be determined using:

$$H[k] = \frac{G_{xy}[k]}{G_{xx}[k]}$$  \hspace{1cm} (7)

where \( G_{xy}[k] \) is the cross power spectrum between the input, \( X[k] \), and the response of the system, \( Y[k] \). The transfer function is useful for isolating the structure and determining its dynamic properties. A common application is to consider the vibrations recorded at the foundation level of a structure as the input motion and the motion recorded at a point within the structure as the response. The transfer function between these two points can be used to estimate the natural frequencies and damping of the structure.

A valuable method for estimating the response of a structure to an incoming ground motion is the response spectrum. The response spectrum is expressed as a pseudo-velocity or pseudo-acceleration versus the natural period (or frequency) of the structure which is modeled by a single-degree-of-freedom (SDOF) system. It is widely used in earthquake engineering for designing earthquake resistant structures and has also been used to estimate the response of structures to blast vibrations (Medearis, 1976; Dowding, 1996). The response spectrum may be calculated using the convolution

Duhamel integral:

\[
\delta(t) = -\frac{1}{\omega_n^2} \int_0^t \ddot{u}(\tau) e^{-\beta \omega_n (t-\tau)} \sin[\omega_d (t-\tau)] d\tau
\]  

(8)

where \(\delta(t)\) is the relative displacement compared to the ground, \(\omega_n\) is the circular natural frequency of the SDOF system, \(\omega_d\) is the damped circular natural frequency, \(\beta\) is the fraction of critical damping, and \(\ddot{u}(t)\) is the particle acceleration of the ground surface. A similar expression can be used if the particle velocity is used as the input motion. The pseudo velocity is calculated using the maximum relative displacement, \(\delta_{\text{max}}\), and the assumption of harmonic motion:

\[
S_v = \omega_n \delta_{\text{max}}
\]  

(9)

Additional information on signal processing and analysis can be found in Bendat and Piersol (1989), Oppenheim and Schafer (1989), and Santamarina and Fratta (1998).

HUMAN SENSITIVITY AND IMPACT

Several ISO standards (ISO 2631-1, 1997; ISO 2631-2, 1989; ISO 6897, 1984; ISO 10137, 1992) prescribe techniques for measurement, analysis, and interpretation of vibration data to assess the impact on human activity and health. The standards were developed to "simplify and standardize the reporting, comparison, and assessment of vibration conditions." The essential components of these techniques are summarized in the following sections.

Measurement

Transducers used to measure the impact of vibrations on humans are to be placed "at the interface between the human body and the source of its vibration" (ISO 2631-1, 1997). In instances where the interface is a rigid surface, the transducer may be placed immediately adjacent to the human body. For non-rigid surfaces (e.g., a cushion), the transducer must be placed between the surface and the human body in such a way that the interaction between the two is not significantly altered. Usually, this requires a mount which conforms to the human body. The transducer(s) should be oriented to coincide with the coordinate system shown in Fig. 3. Measurements of particle acceleration are preferred, but particle velocity time histories may also be recorded and differentiated to obtain acceleration.

Analysis

The impact of vibrations on humans may be evaluated using a weighted root-mean-square (rms) acceleration defined as:

\[
a_w^w(t) = \sqrt{\frac{1}{T} \int_0^T a_w^2(t) dt}
\]  

(10)

where \(a_w(t)\) is the weighted acceleration time history in \(\text{m/sec}^2\) and \(T\) is the duration of the measurement in seconds. In practice, it is more convenient to calculate the weighted rms acceleration in the frequency domain using:

\[
a_w = \sqrt{\sum W_i a_i^2}
\]  

(11)

where \(W_i\) is the weighting factor for the \(i\)th frequency band and \(a_i\) is the magnitude of the rms acceleration of the \(i\)th frequency band. The frequency dependent weighting factors for measurements in the \(z\) direction are shown in Fig. 4. ISO (1997) defines weighting factors for other directions also.

For transient vibrations, the weighted rms acceleration may be misleading because it will underestimate the severity of the vibrations. The crest factor is used as an indicator of this...
situation and is defined as the ratio of the peak value of the weighted acceleration time history to the weighted rms acceleration:

\[
\text{Crest factor} = \frac{\max[|a_w(t)|]}{a_w} \tag{12}
\]

If the crest factor is less than or equal to 9, the use of the weighted rms acceleration is sufficient. For crest factors which exceed 9, two alternatives are recommended to more accurately characterize the vibrations. The first alternative is the running rms method in which the rms acceleration is integrated over a shorter time interval to better capture transient events:

\[
a_w(t_0) = \sqrt{\frac{1}{\tau} \int_{t_0-	au}^{t_0} a_w^2(t) \, dt} \tag{13}
\]

where \( t_0 \) is the time of observation and \( \tau \) is the integration time (\( \tau = 1 \) sec is recommended). The maximum transient vibration value (MTVV) is determined as:

\[
\text{MTVV} = \max(a_w(t_0)) \tag{14}
\]

ISO (1997) suggests that if

\[
\frac{\text{MTVV}}{a_w} > 1.5 \tag{15}
\]

then the transient portion of vibrations may control human response.

The second alternative method to be used if the crest factor exceeds 9 is the fourth power vibration dose value:

\[
\text{VDV} = \frac{4}{1.75} \int_{t_0}^{t_0+T} a_w^4(t) \, dt \tag{16}
\]

ISO (1997) further suggests that if:

\[
\frac{\text{VDV}}{a_w T^{1/4}} > 1.75 \tag{17}
\]

then the transient portion of the vibrations may control human response.

**Interpretation**

ISO (1989) provides guidelines for assessing the impact of construction vibrations on occupants of nearby buildings based on the weighted rms acceleration. Figure 5 shows the base curve which "represent magnitudes of approximately equal human response with respect to human annoyance and/or complaints about interference with activities."

![Graph](image_url)

**Fig. 5 Vibration Criteria for Human Occupants of Buildings - Combined Direction (from ISO, 1989)**

For the specific locations shown in Table 3, the base curve is multiplied by the factor in the table. Curves corresponding to these multiples are also shown in Fig. 5. Interested readers should refer to ISO 2631-2 for additional details concerning the use of these factors.

Criteria involving the maximum transient vibration value (MTVV) and fourth power vibration dose value (VDV) are still under development. Finally, for low-frequency excitation less than 1 Hz, ISO 6897 (1994) provides criteria for maximum tolerable vibration levels for humans.

**BUILDING DAMAGE**

**Measurement**

The placement and coupling of sensors are key parameters that influence the accuracy and usefulness of the data used to assess the impact of vibrations on nearby structures. For measuring incoming ground vibrations the sensors should be placed as close to the foundation of the structure as practical. A convenient, accessible point is often on a main, load-bearing wall at ground level (ISO, 1990, 1992). The motions recorded at these locations on or near the foundation of the structure will differ from free-field ground motions due to

soil-structure interaction effects (Massarch, 1993; ISO, 1996),
but they will more accurately reflect the motions input to the structure. The axes of the sensors are typically aligned with the major axes of the structure.

For direct measurements of the response of a structure to vibrations, sensors should be placed within the structure. Two types of motion which often cause damage to structures are shear and flexural (bending) deformation of walls and floors as illustrated in Fig. 6. Shear deformations are best measured using triaxial transducers placed in the corners of the structure (Siskind et al., 1980; ISO, 1990). Flexural vibrations of walls should be measured using transducers placed at the mid-span of the wall where the amplitude of the vibrations will be the largest. Although the latter type of motion does not often result in damage to the structure, flexural vibrations of walls are frequently responsible for causing window rattling and other effects disturbing to human occupants of the building (Siskind et al., 1980).

Proper coupling between the transducer and the surface being monitored is also important for making accurate measurements. The mounting system should be stiff and light so that the resonant frequency of the mounting system is large compared to the frequency range of the vibrations. For ground vibration measurements, transducers must be placed (in order of preference) on the ground surface (after removing vegetation), mounted on a spike driven into the ground, or buried below the ground surface. In the latter case, the transducer should be buried to a depth not less than three times the dimension of the transducer (ISO, 1990).

For measuring vertical vibrations, the use of longer spikes and burial improves the coupling between the ground and the transducer (Krohn, 1984). Krohn found that the resonant frequency of the mounting system ranged from approximately 100 Hz to 500 Hz for vertical motion, and thus is greater than the frequencies of interest for many construction vibration measurements (see Table 1). For horizontal vibrations, the coupling is strongly affected by the height of the transducer above the ground surface because of the rocking motion of the transducer (Krohn, 1984). When mounting a transducer on a spike, care should be taken to make sure that the bottom of the transducer is in contact with the ground surface to minimize the potential for rocking. Krohn determined that the resonant frequency was as low as 30 Hz when a 1-cm gap existed between the bottom of the geophone and the ground surface. If the resonant frequency of the mounting system is within the range of frequencies of interest, the accuracy of the vibration measurements will be adversely affected.

For measurements on surfaces within a structure or on hard surfaces such as rock, asphalt, or concrete, transducers may be attached using (in order of preference) double-sided tape, wax, magnetic mounts, adhesives, or mounting studs. Mounting transducers on compliant surfaces such as carpeting should be avoided. Additional information on mounting techniques can be found in Bradbury and Saller (1997).

For assessing the response of larger structures, measurements should be made every fourth floor and on the highest floor (ISO, 1990). For structures large in plan, measurements should be made at 10 m horizontal intervals along the length of the structure (ISO, 1990). Simultaneous measurement of vibrations at different locations also allows transfer functions to be determined for evaluating amplification or other filtering effects introduced by the structure.

Fig. 6  Types of Deformation in Structures (from Siskind et al., 1980).

For measuring vertical vibrations, the use of longer spikes and burial improves the coupling between the ground and the transducer (Krohn, 1984). Krohn found that the resonant frequency of the mounting system ranged from approximately 100 Hz to 500 Hz for vertical motion, and thus is greater than the frequencies of interest for many construction vibration measurements (see Table 1). For horizontal vibrations, the coupling is strongly affected by the height of the transducer above the ground surface because of the rocking motion of the transducer (Krohn, 1984). When mounting a transducer on a spike, care should be taken to make sure that the bottom of the transducer is in contact with the ground surface to minimize the potential for rocking. Krohn determined that the resonant frequency was as low as 30 Hz when a 1-cm gap existed between the bottom of the geophone and the ground surface. If the resonant frequency of the mounting system is within the range of frequencies of interest, the accuracy of the vibration measurements will be adversely affected.

For measurements on surfaces within a structure or on hard surfaces such as rock, asphalt, or concrete, transducers may be attached using (in order of preference) double-sided tape, wax, magnetic mounts, adhesives, or mounting studs. Mounting transducers on compliant surfaces such as carpeting should be avoided. Additional information on mounting techniques can be found in Bradbury and Saller (1997).

The type of mounting does not strongly influence the accuracy of the recorded motion when the maximum particle
accelerations are less than 0.3 g (Dowding, 1996). When accelerations are between 0.3 g and 1.0 g, the transducer should be buried for ground vibration measurements or securely coupled to other measurement surfaces to obtain accurate measurements. When accelerations exceed 1.0 g, the transducers must be buried or rigidly attached to the structure. Siskind and Stagg (1985) suggest bolting, clamping, or burying transducers when ground accelerations are expected to exceed 0.2 g. ISO (1990) also recommends that transducers be buried if the acceleration exceeds approximately 0.2 g.

Analysis

The particle velocity of either the ground surface outside of a structure or structural components (e.g., walls, floors, etc.) within the structure is the kinematic parameter most often used to assess possible structural damage. The simplest analysis is to record the peak particle velocity on the ground surface and associate it with a frequency obtained from adjacent zero crossings, Fourier-based spectra, or response spectra. Siskind et al. (1980) recommend that the largest spectral peak and all others greater than one-half the magnitude of the largest peak be taken into account. Dowding (1996) recommends considering peaks that are within 0.7 of the peak spectral amplitude. It is important to note that in this context, the response spectrum is used only as a means of identifying the predominant frequencies in a signal and not as an estimate of structural response.

If a more detailed analysis of the impact of vibrations on a structure is required, the response of the structure may be measured directly or estimated using a response spectrum. In the latter case, the natural frequencies and damping ratios of the structure should be measured using transfer functions between the foundation and other points within the structure. If transfer function measurements are not possible, Dowding (1996) and ISO (1990) provide guidelines for estimating the natural frequency and damping of a variety of structure types.

For simple structural shapes such as a full section rectangular beam, the following expression can be used to estimate the maximum bending stress in the beam as a function of the maximum particle velocity measured on the beam (ISO, 1990):

\[ \sigma_{\text{max}} = \sqrt{\frac{E \cdot \rho \cdot \frac{3}{G_{\text{tot}}} \cdot G_{\text{beam}} \cdot k \cdot v_{\text{max}}}{3}} \]  \hspace{1cm} (18)

where \( E \) is the Young’s modulus, \( \rho \) is the mass density, \( G_{\text{tot}} / G_{\text{beam}} \) is the ratio between the total distributed load on the beam and the self weight of the beam \((G_{\text{tot}} = G_{\text{beam}} + G_{\text{other}}\)), \( k \) is a mode coefficient \((1.0 < k < 1.33)\) which depends on the boundary conditions, and \( v_{\text{max}} \) is the maximum particle velocity measured on the beam.

ISO (1990) provides qualitative guidelines for determining which types of structures are most susceptible to vibration-induced damage. The classification scheme is based on the following four factors:

- Type of construction
- Type of foundation
- Type of soil
- Societal importance of the structure

These guidelines are useful in defining the scope of the vibration measurements for a particular structure.

One popular vibration criterion is the frequency-dependent limits proposed by the U.S. Bureau of Mines (Siskind et al., 1980) based on an extensive study of damage to residential structures from surface mine blasting. Siskind et al. (1980) found that horizontal peak particle velocity measured on the ground outside of a structure correlated well with “threshold damage” defined as cosmetic damage (e.g. cracking) within the structure. Although other descriptors of the ground motion were considered, peak particle velocity was chosen for its effectiveness and simplicity (Siskind, 1996). The vibration criteria are presented in a simple form (Table 4) and in a more complex form (Fig. 7) with transitions between frequency ranges. The lower limits at frequencies less than 40 Hz reflect the fact that the structural and mid-wall resonant frequencies are usually within this range for residential structures.

Both methods require an estimate of the dominant frequencies contained in the vibration time history. Siskind (1996) reviewed several methods of determining the frequency including those described above and found no significant differences among the methods.

Representative standards used in other countries are shown in Table 5.
Several researchers advocate the use of structural response for establishing maximum allowable vibration criteria. If direct measurements of the response of the structure are unavailable, the maximum particle velocities can be estimated using a pseudo-velocity response spectrum. Medearis (1976) recommended a maximum allowable pseudo-velocity of 38 mm/sec. Siskind (1996) has suggested an interim value of the maximum allowable pseudo-velocity equal to 50 mm/sec until additional studies warrant a different value. Dowding (1996) examined response spectra for blast vibrations which caused cracking of drywall and plaster walls in residential structures. On the basis of those case studies, Dowding has recommended a displacement-controlled region be used as the criterion for preventing cosmetic damage.

ISO (1996) specifies that transducers should be positioned on the equipment, on the isolation system if present, and on the floor adjacent to the equipment. Measurements performed in this manner allow transfer functions to be determined between the floor and the equipment. Particle velocity or acceleration should be recorded in three orthogonal axes using transducers securely mounted to the measurement surface as described previously.

For transient vibrations, ISO (1996) recommends that the peak particle velocity or acceleration be determined along with the period (frequency) of the peak value found by examining zero crossings. Response (shock) spectra should also be calculated. For intermittent vibrations, the repetition rate should also be determined.

For continuous vibrations, the peak particle velocity values and rms values for different time intervals should be determined. Averaged power spectra should also be calculated to allow identification of dominant frequencies.

Ungar and Gordon (1985) reviewed vibration criteria from a large number of equipment manufacturers to develop the recommended limits shown in Fig. 9.

Ungar and Gordon have included several ISO limits for human activities including workshop, office, and residential locations. Note that the limits for sensitive equipment are significantly less than those tolerable or perceptible by humans.

CONCLUSIONS

Vibrations from man-made sources including construction activities, blasting, rail and vehicular traffic, and machinery can adversely impact humans, structures, and vibration-sensitive equipment. Comparisons between data from different sources is often hindered by the lack of consistent measurement, analysis, and interpretation standards. The following guidelines are suggested to facilitate these comparisons:

- Care should be taken in selecting and mounting transducers for each application. The effects of the measurement system should be accounted for by employing a frequency response function with both amplitude and phase information to correct for the instrument response.

- Standard time domain and frequency domain signal processing techniques should be used to analyze the vibration data. These techniques range from simple determination of the peak particle motion and associated frequency to advanced spectral estimation methods and time-frequency analyses for non-stationary signals.

- Use definitive and prescriptive standards for assessing the impact of vibrations on human activity. Weighted rms acceleration, maximum transient vibration value (MTVV), and fourth power vibration dose value (VDV) are all precisely defined measures of the impact on humans. Maximum allowable vibration limits are specified by ISO (1989, 1997).

- Use peak particle velocity measured on the ground outside of structures and simple frequency estimates based on zero crossings in conjunction with the U.S. Bureau of Mines (Siskind et al., 1980) frequency-dependent vibration criteria to assess the likelihood of cosmetic damage to structures. Response spectra are desirable from a structural response view, and should also be calculated to help develop appropriate damage criteria.

- Vibration limits for sensitive electrical, optical, and mechanical equipment used in testing and manufacturing are more stringent than vibration limits for humans and buildings. In the absence of specific criteria from an equipment manufacturer, use the vibration limits proposed by Ungar and Gordon (1985) for assessing the impact of vibrations on equipment.
